Quantum Reed-Muller (Steane $[[7,1,3]]$) Code

1. Introduction

Quantum Reed-Muller (RM) codes are a powerful family of CSS codes constructed from classical RM codes or their punctured versions. The Steane $[[7,1,3]]$ code is a prominent punctured RM code (specifically derived from the classical Hamming $[7,4,3]$ code).

Unlike the Shor code, which uses 9 qubits to correct a single error by concatenating repetition codes, the QRM (Steane) code achieves the same distance ($d=3$) using only 7 qubits. Furthermore, because it is a **CSS code**, its X and Z error correction protocols are perfectly symmetrical, and it allows for transversal implementation of certain Clifford gates.

1.1 The Parity Check Matrix

The stabilizer generators are defined by the classical Hamming parity check matrix H:

$$H = \begin{pmatrix} 1 & 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{pmatrix}$$

Because this matrix is self-orthogonal ($HH^T = 0 \pmod 2$), we can use the exact same matrix for both our Z-stabilizers (to detect X errors) and X-stabilizers (to detect Z errors).

- Each row of H defines a stabilizer generator.
- For Z-checks: Row 1 means we check the parity of qubits 0, 3, 5, and 6 using Z operators.
- For X-checks: Row 1 means we check the parity of the same qubits using X operators.

---

2. Qiskit Implementation

This implementation builds the complete 13-qubit system (7 Data + 6 Ancilla) for explicit syndrome extraction. We use 3 ancillas for the Z-checks and 3 ancillas for the X-checks.

In [1]:
```
%pip install numpy==1.26.4 scipy==1.12.0

import numpy as np
import matplotlib.pyplot as plt
from qiskit import QuantumCircuit, QuantumRegister, ClassicalRegister
from qiskit_aer import AerSimulator
from scipy.optimize import fsolve
```

```python
print("Imports successful")
```

```

---

3. Performance Simulation

To evaluate the performance of the Steane $[[7, 1, 3]]$ code, we inject independent depolarizing noise (X, Y, or Z) on all 7 qubits.

Because the CSS construction separates X and Z tracking, the code can occasionally correct weight-2 errors if they occur in different bases (for example, an X error on q_0 and a Z error

on q_1). However, the theoretical worst-case bound assumes the code fails if *any* 2 or more errors occur across the 7 qubits.

We will compare our simulated logical error rate against the theoretical worst-case failure probability:

$$P_{theory} = 1 - (1-p)^7 - 7p(1-p)^6$$

In [ ]:
```
def apply_random_noise(qrm_instance, p):
    for qubit_idx in range(7):
        if np.random.random() < p:
            error_type = np.random.choice(['X', 'Y', 'Z'])
            if error_type == 'X': qrm_instance.qc.x(qrm_instance.data[qubit_idx])
            elif error_type == 'Y': qrm_instance.qc.y(qrm_instance.data[qubit_idx])
            elif error_type == 'Z': qrm_instance.qc.z(qrm_instance.data[qubit_idx])
